Inelastic Electron Scattering and the Multi-Regge Model

Michael J. Creutz†
Stanford Linear Accelerator Center, Stanford University, Stanford, California 94305
(Received 11 June 1969)

We investigate the multi-Regge model in the kinematic region where the four-momentum of one initial particle is large and spacelike. These kinematics occur in inelastic electron scattering through single virtual photon exchange. Contradicting present data, we predict a rapid falloff in the cross section as the virtual particle becomes more spacelike.

After radiative corrections, inelastic electron scattering measures the total cross section for virtual photons as a function of the photon mass as well as its energy. This freedom of varying a particle mass is a new feature not yet available in other reactions; therefore, this process has recently attracted much theoretical interest. Denote the total cross sections for transverse and longitudinal virtual photons incident on spin-averaged protons by \( \sigma_T \) and \( \sigma_L \), respectively, let \( \nu \) be the photon lab energy, and let \( p_0^2 \) be the square of the photon four-momentum. Bjorken has shown that, as \( \nu \) and \( p_0^2 \) become large with the ratio \( \nu/p_0^2 \) constant, it is likely that \( \sigma_T \) and \( \sigma_L \) have finite, as opposed to infinite, limits of value dependent on this ratio \( \nu/p_0^2 \). Current data seem to indicate that this limit is nonvanishing. Most of the recent interest in the subject concerns the behavior of this limit as a function of \( \nu/p_0^2 \).

The multi-Regge model (MRM) has drawn interest as a possible description for highly inelastic hadronic collisions. We wish to relate the MRM to inelastic electron scattering by discussing the behavior of the MRM as the four-momentum \( p_1 \) of an initial particle becomes large and spacelike. In this way, we hope to gain some insight into the behavior of Bjorken's limit functions. In particular, we ask if the above-discussed behavior for \( \sigma_L \) and \( \sigma_T \) is consistent with the simple MRM. As we are studying the MRM in a region quite different from where it is usually applied, any shortcomings of the model here will not invalidate the model in its usual application to real hadronic reactions.

Essentially, our calculation follows the work of Halliday and Saunders, except that we allow one initial mass to be variable. For simplicity we treat all particles as spinless. Figure 1 shows our kinematics. A virtual particle of momentum \( p_1 \) collides with a particle of momentum \( p_2 \) and unit mass (\( p_0^2 = 1 \)). The final state consists of \( n \) identical particles labeled with momenta \( q_i, i = 1, \ldots, n \), and all of unit mass (\( q_i^2 = 1 \)). Define

\[
\begin{align*}
q_i &= (q_i + q_{i+1})^2, \\
t_i &= (p_1 - \sum_{j=1}^{i} q_j)^2,
\end{align*}
\]

\( s = (p_1 + p_2)^2 = (\text{c.m. energy})^2, \)

\( v = p_1 \cdot p_2 = \frac{1}{2} (s - 1 - p_1^2) \)

The energy of \( p_1 \) in the rest frame of \( p_2 \).

The simple form of the MRM which we shall use says that when all the \( s_i \) are large and the \( |t_i| \) small, the amplitude for the process is approximately of the form

\[
T_n = G(p_1^s,q_1)G(q_1,q_2)\cdots G(q_{n-1},q_n)\alpha(t_n)\cdots \alpha(t_1).
\]

Here the \( G \)'s are unspecified vertex functions and \( \alpha(t_i) \) is the trajectory function of the exchanged Reggeon. We consider only one type of Reggeon and take

\[
\alpha(t_i) = j_0 + j_1 t_i, \quad j' \neq 0.
\]

For each of the \( n! \) orderings of the \( q_i \), there is a similar expression for \( T_n \) valid when the respective \( s_i \) are large and \( t_i \) small. It will be clear later that these \( n! \) kinematic regions are disjoint, giving no interference between them; thus, only one ordering need be considered. The factor of \( n! \) arising from these different orderings is canceled by the \( 1/n! \) occurring in the phase space for \( n \) identical particles.

---

**Fig. 1. Kinematics for the inelastic scattering.**
The MRM contribution to the total cross section from \( n \)-particle production is therefore given by
\[
\sigma_{\text{tot}} = \frac{1}{v_{\text{rel}}(2\pi)^{n-1}} \left( \frac{d\Phi}{2\pi} \right)^{n-1} | T_n |^2, \tag{4}
\]
where
\[
d\Phi = \delta^4(p_1 + p_2 - \sum_{i=1}^n q_i) \prod_{i=1}^n [\delta^4(q_i^2 - 1) d^4 q_i],
\]
\[
\delta^4(q_i^2 - 1) = \delta(q_i^2 - 1), \quad \delta(x) = 1, \quad x > 0,
\]
\[
= 0, \quad x < 0,
\]

\( p_{\text{rel}} \) = energy of \( p_1 \), and \( v_{\text{rel}} \) = relative velocity of \( p_1 \) and \( p_2 \). We work in a frame where \( p_1 \) and \( p_2 \) are parallel. In the limit \( \nu \to \infty \) (note \( s \geq 2\nu \geq 1 \) implies \( -p_i^2 \leq 2\nu \)),
\[
1/v_{\text{rel}}(2\pi)^{n-1}(2\pi)^{n-1} = 1/4\nu.
\]

To simplify the integral over phase space, let us change to a set of variables introduced by Sudakov\(^a\) and apply them to this problem, following closely Halliday and Saunders.\(^b\) To define these variables, introduce two new momenta
\[
\begin{align*}
p_{i}' &= p_i - (\nu - (\nu^2 - p_i^2)^{1/2}) p_2, \\
p_{i}'' &= p_i - (1/\nu^2)[(\nu - (\nu^2 - p_i^2)^{1/2}) p_1.
\end{align*}
\tag{6}
\]
These momenta have the useful property \( p_{i}'^2 = p_{i}''^2 = 0 \). In the limit \( \nu \to \infty \), we have
\[
\begin{align*}
p_{i}' &= p_i - (\nu^2/2\nu) p_2, \\
p_{i}'' &= p_i - (1/2\nu) p_1,
\end{align*}
\tag{7}
\]
\( p_{i}' \cdot p_{i}'' = 0 \).

Now we define the Sudakov variables \( \{ \alpha_i, \beta_i, K_i \} \) by
\[
q_i = \alpha_i p_i' + \beta_i p_i'' + K_i,
\tag{8}
\]
where \( K_i \) is the transverse part of \( q_i \). A little algebra shows that, in the limit \( \nu \to \infty \) (allowing \( -p_i^2 \) comparable to \( \nu \)),
\[
dq_i = \nu d\alpha_i d\beta_i d^2 K_i,
\tag{9}
\]
\[
\delta^4(q_i^2 - 1) = \frac{1}{2\nu} \delta(\alpha_i - \frac{1 - K_i^2}{2\nu}), \tag{10}
\]
\[
\delta^4(p_1 + p_2 - \sum_{i=1}^n q_i) = \delta^4(\sum_{i} K_i) \delta(\sum_{i} \alpha_i - 1) 
\]
\[
\times \delta\left(\sum_{i} \beta_i - \frac{1 - p_i^2}{2\nu}\right), \tag{11}
\]
\[
s_i = 2\nu (\alpha_i + \alpha_{i+1})(\beta_i + \beta_{i+1}), \tag{12}
\]
\[\begin{align*}
l_i &\approx (\sum_{j=1}^i K_j)^2 - 2\nu \sum_{j=i+1}^n \alpha_j + \frac{1}{2\nu} \sum_{j=i+1}^n \alpha_j \beta_j \\
&\quad + \frac{1}{2\nu} \sum_{i=j+1}^n \alpha_j + \frac{1}{2\nu} \beta_j \cdot p_i^2.
\end{align*}
\tag{13}
\]
Note that \( \alpha_i \) and \( \beta_i \) are all positive because of \( \delta^4(q_i^2 - 1) \). In terms of these variables, our integral becomes
\[
\sigma_{\text{tot}} = \frac{1}{2^{n+2}(2\pi)^{3n-4}} \int \prod_{i=1}^n [d\alpha_i d\beta_i d^2 K_i, \delta(\alpha_i) \\
\times \delta\left(\alpha_i - \frac{1 - K_i^2}{2\nu}\right) \delta^4(\sum_{i} K_i) \delta(\sum_{i} \alpha_i - 1) 
\]
\[
\times \delta\left(\sum_{i} \beta_i - \frac{1 - p_i^2}{2\nu}\right) |G(p_1^2, l_i)|^2 |G(l_{n-1}, 1)|^2 
\]
\[
\times \prod_{i=1}^{n-2} |G(l_{i+1}, 1)|^2 \prod_{i} |s_i^{2\nu} q_i^{2\nu} l_i| \tag{14}
\]

In the region where all the \( s_i \) are large, the factor \( s_i^{2\nu} l_i \) in (14) gives a rapid \( l_i \) dependence. If the \( G_i^2 \) s are smooth and polynomially bounded, this factor will cause small \( l_i \) to dominate the cross section. Furthermore, when the \( s_i \) are large enough, the factor \( s_i^{2\nu} l_i \) will dominate all \( l_i \) dependence.

Restricting ourselves to this region of large \( s_i \), we can immediately do the \( K_i \) integrals, with the result that
\[
\sigma_{\text{tot}} = \frac{1}{2^{n+2}(2\pi)^{3n-4}} \left( \frac{\pi}{2\nu} \right)^{n-1} \times \int \prod_{i=1}^n [d\alpha_i d\beta_i d^2 K_i, \delta(\alpha_i) \\
\times \delta\left(\alpha_i - \frac{1 - K_i^2}{2\nu}\right) \delta(\sum_{i} \alpha_i - 1) 
\]
\[
\times \delta\left(\sum_{i} \beta_i - \frac{1 - p_i^2}{2\nu}\right) |G(p_1^2, l_i)|^2 |G(l_{n-1}, 1)|^2 
\]
\[
\times \prod_{i=1}^{n-2} |G(l_{i+1}, 1)|^2 \prod_{i} |s_i^{2\nu} q_i^{2\nu} l_i| \prod_{i} \ln s_i \tag{15}
\]

\[
\text{where now}
\]
\[
s_i = 2\nu (\alpha_i + \alpha_{i+1})(\beta_i + \beta_{i+1}),
\]
\[
l_i = -2\nu \left( \sum_{j=i+1}^n \alpha_j \right) \left( \sum_{j=i+1}^n \beta_j \right) 
\]
\[
\quad + \frac{1}{2\nu} \sum_{i=j+1}^n \alpha_j + \frac{1}{2\nu} \beta_j p_i^2.
\tag{16}
\]

Since \( s_i \) is large and \( \alpha_j \beta_j \approx 1/2\nu \), we have
\[
\frac{s_i}{\alpha_{i+1}} \gg 1.
\tag{17}
\]

However,
\[
\frac{p_1^2}{2\nu} - \sum_{j=1}^{i} \beta_j + i\leq -2\alpha_{i+1} \beta_i = -\alpha_{i+1} \alpha_i
\]
\[
\Rightarrow \frac{\alpha_i}{\alpha_{i+1}} \beta_i \gg 1
\]
(19)
and
\[
l_i = p_i^2 \alpha_{i+1} - p_i^2 / 2\nu.
\]
(20)
This shows that the \(\alpha_i\) are a decreasing sequence and therefore demonstrates our earlier claim that other particle orderings have disjoint kinematic regions for the MRM. Rememering that \(i, \alpha_i \approx 1\), we see from (19) that
\[
\alpha_1 \approx 1, \quad \beta_1 \approx 1 / 2\nu.
\]
(21)
Similarly, since \(\sum_i \beta_i = 1 + p_1^2 / 2\nu\),
\[
\beta_n \approx 1 + p_1^2 / 2\nu = s / 2\nu, \quad \alpha_n \approx 1 / s.
\]
(22)
From these relations, clearly,
\[
\prod_i s_i = \alpha_1 \alpha_n = s
\]
(23)
and
\[
l_i = p_i^2 \prod_{j<i} s_j^{-1} - p_i^2 / 2\nu.
\]
(24)
Let us define \(s_i, \gamma\) by
\[
s_i = s^{\gamma_i}, \quad p_i^2 = s^{\gamma_i - 1}.
\]
(25)
Since \(\prod_i s_i = s\), we have \(\sum_i \gamma_i = 1\). We have required \(s_i \to \infty\), so we must keep
\[
y_i \geq \epsilon > 0
\]
(26)
where
\[
1 / \epsilon = o(\ln s).
\]
(27)
Furthermore \(s_i \leq s\) implies \(y_i \leq 1\). The variable \(\gamma\) can run from \(-\infty\) to \(+\infty\) as \(p_i^2\) runs from \(0\) to \(2\nu\), although \(\gamma\) becomes large only very near these values of \(p_i^2\). The usual limit \(p_i^2 / \nu = \text{const}\) where \(\nu \to \infty\) corresponds to \(\gamma \to 1\).

In terms of these new variables
\[
s_i s_i^{-\gamma_i} \ln s_i s_i^{-\gamma_i} s_i^{-\gamma_i} = \theta_i \sum_i \gamma_i - \gamma_i \prod_i s_i^{\gamma_i - 1},
\]
(28)
This \(\theta\) function represents a shrinkage with increasing \(\gamma\) of the kinematic region for the MRM. It means that in order to keep \(k_i\) small, \(s_i\) must be larger than \(p_i^2\).

Unless \(n = 2\), we have \(s_i < s\) implying \(y_i < 1\). The \(\theta(1 - \gamma)\) reduces the multiplicity \(n\) as \(\gamma\) increases until for \(\gamma = 1\) only \(n = 2\) will contribute appreciably. Let us briefly discuss the case \(\gamma < 1\) before going on to \(\gamma = 1\) and the Bjorken limit.

We change integration variables from the \(\alpha_i\) to the \(y_i\) using
\[
y_i = \ln s_i / \ln s,
\]
(29)
This gives the result
\[
\sigma_{\text{tot}} = \frac{s^{2n-2}}{\ln s} \left| G(p_1^2, 0) \right|^2 G(0, 1) \left| \frac{G(0, 0)}{2\pi^3} \right| n^{2-n} \frac{1}{32\pi^2 j^{n-2}} J_n(\epsilon, \gamma),
\]
(30)
where
\[
J_n(\epsilon, \gamma) = \int \frac{dy_1 \cdots dy_{n-1}}{s^n} \delta(\sum_i y_i - 1) \theta(1 - \gamma).
\]
(31)
With \(p_1^2 = 1\), this is just the result of Halliday and Saunders. Note that \(J_n(\epsilon, \gamma) = 0\) unless \(\gamma + (n-2)\epsilon < 1\). This means that
\[
n < 2 + \frac{1}{n-2}\epsilon = 2 + O[\ln(s / p_1^2)].
\]
(32)
This shows the decrease in multiplicity mentioned above.

As we go to the Bjorken limit of \(\nu \to \infty\) with \(\nu / p_1^2\) fixed, the parameter \(\gamma\) goes to \(1\). In this limit, we have the remarkable result that final states of two hadrons will dominate the cross section. This contribution from \(n = 2\) is easily evaluated, giving
\[
\sigma_{\text{tot}} = \sigma_{\text{tot}}^2 = \frac{1}{32\pi^2 j^{n-2}} \frac{s^{2n-2}}{s^n} \left| G(p_1^2, 0) \right|^2 \frac{1}{2\omega(2\omega - 1)} \left[ G(0, 0) \right]^2
\]
(33)
where
\[
\omega = -\nu / p_1^2.
\]
(34)
The expression \(1 / 2\omega(2\omega - 1)\) occurring in (32) is the minimum value of \(-\nu\) in the limit of large \(\nu\). Because it can approach this value only for \(n = 2\), two final hadron states should dominate the cross section. Equation (33) is the prediction of the MRM for the cross section in the Bjorken limit with \(\omega < \infty\).

If we put in a typical \(j_0 = \frac{1}{2}\), then for fixed \(\omega\),
\[
\sigma_{\text{tot}} \sim \left( \frac{-p_1^2}{\ln p_1^2} \right) \frac{2\omega - 1}{2\omega(2\omega - 1)} \left( G(p_1^2, 0) \right)^2.
\]
(35)
Bjorken predicts that this should go to a constant as \(p_1^2 \to \infty\). Indeed, the first factor is slowly varying for \(\omega > 1\). However, from experience with elastic electromagnetic form factors, one might expect
\[
\sigma_{\text{tot}} \sim \left( \frac{1}{2\omega(2\omega - 1)} \right)^2 \left( \frac{p_1^2}{2\omega(2\omega - 1)} \right)^4
\]
(36)
This falloff is quite rapid and no such effect has been seen as yet in the data. This indicates trouble with the model unless something drastic happens to the asymptotic behavior of $G(p_i,t)$ as $t$ is varied from the physical mass of the exchanged particle to $t = -1/2\omega(2\omega - 1)$. When $\omega > 1$, this extrapolation is not large and we cannot theoretically justify such a change in behavior.

It may be that the data are not yet in the asymptotic region. In present experiments, $-p_i^2$ is not large compared to the above mentioned extrapolation of $t$. Assuming that this is the case, and that the model is still applicable, we can make a simple prediction on final-momentum distributions.

If we define the final-particle ordering for multi-

particle-production events by decreasing lab momentum (decreasing $\alpha_i$), we should find most events with $s_1 = (q_1 + q_2)^2 > -p_1^2$, whereas further $s_i = (q_i + q_{i+1})^2$ will tend to lower values. Furthermore, as we increase the lab energy $\nu$ with fixed $\omega \neq 0$, the average multiplicity should decrease to two. These are effects that may begin to show up at nonasymptotic energies and should be looked for.

ACKNOWLEDGMENTS

I would like to thank S. Drell, R. Brower, G. Chew, and A. Pignotti for interesting discussions on this subject.

PHYSICAL REVIEW VOLUME 187, NUMBER 5 25 NOVEMBER 1969

Overlapping Resonances in Three-Meson States†

J. ARTHUR SNOKE‡

Physics Department, Yale University, New Haven, Connecticut 06520

(Received 30 June 1969)

We consider a system of three pseudoscalar mesons in which one of the mesons can form a two-particle resonance with either of the other two. The models we discuss include the Lee model, approximations to the Lee model, and a fully relativistic isobar model. As an example for the nonstatic model we discuss the $3\pi$ state containing two overlapping, identical $\rho$ resonances. There have been claims that resonance projections can lead to enhancements in the three-particle mass when there are overlapping two-particle resonances. We show that these enhancements are caused by approximations which are not actually resonance projections, and we show for our models that properly made resonance projections do not lead to enhancements. We discuss briefly some alternatives to the isobar model for treating overlapping resonances.

I. INTRODUCTION

In this paper we consider an example of overlapping resonances, namely, a state containing three pseudoscalar mesons in which one of the mesons can form a two-particle resonance with either of the other two. Experimentally, such a state usually occurs as a subsystem for a final state in a meson-nucleon production reaction, and experimental data are becoming available with good enough statistics to allow a detailed study of such subsystems. Two cases of particular interest are the $3\pi$ system with two identical $\pi$'s either of which can form a $\rho$ with the third $\pi$, and the charged $K\pi\pi$ system which contains the appropriate quantum numbers for one $\rho$ and (at least) one $K^*$. Much of the interest in these particular systems comes from the fact that there are experimentally observed enhancements in the three-particle mass spectrum for both these cases near the overlap threshold, called the $A_1(1080)$ and the $K^*(1300)$, respectively. One of the motivations of this work was to investigate the possibility that such enhancements could be caused merely by the resonance overlap.

In Sec. II A we discuss overlapping resonances in the Lee model and in other static models. The Lee model is of particular interest because it presents the overlapping resonance situation within the context of a completely soluble field theory, and the static kinematics is useful for gaining understanding of some of the mechanisms involved in overlapping resonances. In Sec. II B we develop a nonstatic isobar model using the helicity-state formalism introduced by Wick. The model developed here, although equivalent to other approaches, is particularly simple to work with when calculating total or differential cross sections. As an example we discuss the $3\pi$ case referred to above.
